1 Introduction

The United States has a persistent history of encouraging and enforcing discrimination, oppression, and other forms of prejudice against African Americans, who are often simply characterized as "Black". The turbulent relationship between the Black community and the institutions of government, education, healthcare, law enforcement, social services, and even housing, is a compounded byproduct of historical bylaws—most infamously, the era of Jim Crow laws (c. 1877-1964)—that have yet to be unraveled from the fabric of U.S. American culture and politics.

Racially-motivated violence has been the cornerstone of the Black experience for the entirety of the community's documented history. Paradoxically, Black people are more susceptible to bouts of national trepidation but are expected to show the most resilience. With the additional intersection of gender, Black *women* are especially vulnerable but are often neglected in policies and actions designed to alleviate the stressors of U.S. residents.

In the spring of 2020, the deficit of adequate resources for Black women was proven evident with the surge of COVID-19 and the subsequent deaths of George Floyd and Breonna Taylor. Even with nationwide attention on these issues, Black women continued to suffer in silence under the pretense that they are "strong": perpetually shouldering the burdens of others with no space for their own (Pappas, 2021). Consequently, Black women as a population experience disparities in quality of life that no other group in the U.S. do, most of which can be attributed to social-environmental factors. They are at higher risk for breast cancer, stroke, diabetes, and hypertension; the Black community overall experienced two to three times more complications or death from COVID-19 than the general U.S. population (Menifield & Clark, 2021). Concerning mental health, Black women are half as likely to seek services compared to their white counterparts, and documented studies suggest one reason for this is the lack of cultural competency among providers (Abrams et al., 2018).

In the context of this study, the population of interest is Black women over the age of 18. The barriers previously mentioned have contributed to the marginalization and isolation of Black women in their home lives and in public spaces. By examining potential associations extracted

from respondent data, methods for healthy and impactful coping mechanisms can be identified. Data is derived from a survey conducted in April 2022, to learn how Black women were coping during the pandemic. Approximately 2680 participants responded to 70 questions. In addition to demographic information, the topics covered in the survey included COVID-19, anti-Black racism, depression, anxiety, and coping. The analysis presented in the following sections is driven by structural modeling methods. In lieu of significance testing, the objective of the study is to determine prominent factors that influence the extent to which Black women suffer from depression, anxiety, and other mental health issues.

2 Methodology

2.1 The Data

A survey was conducted via a paid panel to find out how Black women across the United States were coping. Data was collected from April to December 2022, accumulating 2631 respondents. The survey consisted of 70 questions asking about the following domains: COVID-19 (13 questions), Anti-Black Racism (12 questions), Depression (9 questions), Anxiety (7 questions), Coping Methods (13 questions), and Demographic information (16 questions).

The 7 anxiety questions were from the Generalized Anxiety Disorder screening test (GAD-7). Similarly, the questions asking about depression were the screening questions from the Patient Health Questionnaire (PHQ-9) as well as the question asked after the screening. However, the first of the 9 screening question of the PHQ-9 was mistakenly omitted from the survey. To be complete, we estimated each subject's response to this based on their responses to the other 8 screening questions.

The raw data consists of 157 variables and 2631 subjects. With the addition of the first PHQ-9 screening question, the data contained 159 variables. Since this research focuses on Black women, there were questions to screen out participants who were not adult, Black females that consented to the survey. There were 2260 subjects that fit the requirements. Variables that were

irrelevant to analysis were also removed, such as personal information or variables that had been recoded, leaving 81 variables for analysis. The data has also been validated by removing potential duplicates (i.e., a respondent had to restart the survey and was recorded twice); and ensuring values for a given variable are all of the same type (e.g., all values for age are numeric).

Initially, we believed this was sufficient for implementing the methods outlined in the following sections. During preliminary testing, however, two other issues with the data surfaced: missing values and linear dependencies. Factor analysis methods will not do any calculations with any missing values, and often throw an error. They are also susceptible to generating factors with egregious inflated variances if there are variables that can be expressed as linear combinations of others. So, variables and observations that met the following criteria were filtered out:

- Open-ended responses, as they cannot be applied to any statistical modeling methods
- The proportion of NA observations. Each variable either consists of more than 95% empty observations, or less than 15%. In the former case, the variable was omitted. In the latter case, the observations with the NA value(s) were removed.
- Variables that represent composite scores (the sums or averages of other variables), which were causing the redundancy and linear dependence in the data.

The final dataset consists of 66 variables and 1450 subjects. For many applications, this may be a concern, but as the rest of the report will show, this proved beneficial in containing the volume before applying any algorithmic dimension reduction.

2.2 Structural Equation Modeling (SEM)

Structural Equation Modeling (SEM) is a technique for investigating relationships by specifying a model that represents predictions of that theory among plausible constructs measured with appropriate observed variables (Hayduk, Cummings, Boadu, Pazderka-Robinson, & Boulianne, 2007). SEM can be thought of as a combination of regression analysis and factor analysis; it uses latent variables or constructs that are measured by multiple observed variables or indicators. For

example, an SEM model can be used to estimate the association between outcomes, such as levels of depression or anxiety, and underlying attitudes that influence those, such as coping mechanisms and the effects of Covid-19 or anti-Black racism. SEM allows us to include multiple influences, to allow unobserved concepts that control for the observed indicators, to specify how those concepts influence one another, to assess the model's overall compatibility with the data, and to determine how well the model fits the data (Chapman & Feit, 2019).

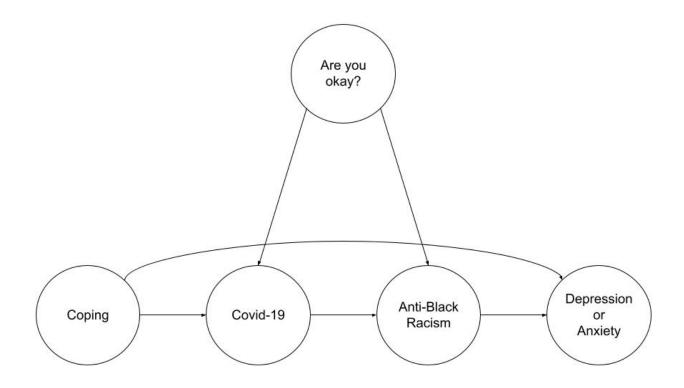

Figure 1: A model measuring levels of depression and anxiety. In this model, coping ability and strategies are associated with Covid-19 and anti-Black racism factors, while the overarching response to *Are you okay?* closely relates to both Covid-19 and anti-Black racism influences, which is then associated with levels of depression and anxiety.

To use SEM as an analysis tool, a graphical path diagram of influences is first created. Then, the strengths of the relationships for each path in the model are estimated. The paths in the model can be categorized as either observed variables (i.e., have data points), or latent variables that may underlie the observed data. A model is then fitted to the data using the structural model paths created. Figure 1 demonstrates how an SEM model can be constructed to investigate the objectives of this study. For example, the COVID-19 latent variable can be observed as survey

items Q1, Q2, and Q3. More complexly, the Coping latent variable can be observed by both survey items and other latent variables (i.e., COVID-19, anti-Black racism, etc.). Upon fitting the SEM model, the strength of the relationships between the latent variables are compared, as well as the degree to which the model fits the observed data. Alternative models may then be fit and compared to the original (full) model.

2.3 Exploratory Factor Analysis (EFA)

In Chapter 8.3 of R For Marketing Research and Analysis, Chapman and Feit (2019) describe Exploratory Factor Analysis (EFA) as a family of techniques used to assess the relationship of constructs (concepts) in surveys and psychological assessments. Factors are regarded as latent variables that cannot be observed directly—as one might in a simple linear model—but are associated through their relationship to other variables. For example, abstract concepts such as intelligence, personal preference, and emotions are not observable independently or empirically. Instead, they are measured with a number of indicators known as manifest variables, which are empirical factors and behaviors (e.g., GPA, survey responses, and so on) that, in tandem, provide an imperfect explanation to the underlying latent variables.

The goal of EFA is to find the degree to which the latent variables account for the observed variance of the manifest variables. The result is similar to Principle Components Analysis (PCA), where linear combinations or mixtures of the initial variables reduce the dimensionality of the data while retaining as much information as possible. What separates EFA from PCA, however, is the interpretability of the loadings on the variables. In other words, EFA optimizes solutions that favor intuition regarding the original variables so one can test whether the data is consistent with expectations.

To find a solution using EFA, the following steps are generally implemented with a variety of tools and techniques:

1. **Determine the number of factors to estimate and test**. In R, this can be done by constructing a *scree plot*—a line plot of the eigenvalues of factors or principal components—and

retaining the factors with an eigenvalue greater than 1.0. An value of 1.0 corresponds to the amount of variance that can be attributed to a *single* independent variable.

- 2. Extract factors for modeling. Determine the variable loadings using PCA, maximum likelihood, or other methods to select the k (limited to the number suggested in Step 1) factors to include and interpret. Trying more than one value of k-none beyond $k \pm 1$ -is recommended to determine which model yields stronger interpretability.
- 3. Rotate the loadings. The purpose of rotation is to determine whether correlation between factors should be allowed. Software cannot interpret the context of the *latent variables* but rotation can assist in deciding if, conceptually, factors should be considered independent or if it makes more sense for them to be related. One of two types of rotations can be applied: *orthogonal* and *oblique*. Orthogonal rotation, as its name implies, assumes that factors *do not* correlate. While this method is the default among most software and languages, it is not always the more plausible. Oblique rotation, on the other hand, assumes that factors can and *do* correlate and considers how.

2.4 Why these methods?

The parameters of interest for this study are depression and anxiety. One might opt for regression methods. However, where regression aims to predict a given variable, we are instead interested in the relationship between variables. Both SEM and EFA aim to explain relationships between variables. Additionally, depression and anxiety cannot be measured directly (i.e., they are latent variables), making these methods good options for our data.

One can see the data has high dimensionality. These methods have also been chosen for dimension reduction. Why, then, do we not use principal component analysis (PCA)? PCA seems like a good option since it is also a dimension reduction technique. However, the goal of PCA is to capture as much variability as possible with linear combinations of the variables, called principal components (PCs). It does not make any model assumptions, whereas EFA and SEM propose models and test whether the data fits those models. With PCA, the PCs cannot be interpreted since there is no underlying structure. Our chosen methods have constructs that are easy to

interpret.

The two methods we have chosen are very similar, but there is a subtle difference. EFA identifies relationships among variables, whereas SEM is used to determine the extent to which assumptions about the relationships among variables are supported by data (Ockey, 2013). In this study, we identify relationships with EFA and assess these relationships using SEM.

3 Results

3.1 Factor Extraction

The process of extracting factors from our data uses the following R packages: nFactors, GPArotation, psych, parameters, performance, and lavaan.

First, the check_factorstructure() function informs us of whether the data is even suitable for factor analysis, based on sampling adequacy and sphericity—whether the correlation matrix of the data is significantly different from an identity matrix.

```
> performance::check_factorstructure(okDat)
# Is the data suitable for Factor Analysis?

- KMO: The Kaiser, Meyer, Olkin (KMO) measure of sampling adequacy suggests that data seems appropriate for factor analysis (KMO = 0.92).

- Sphericity: Bartlett's test of sphericity suggests that there is sufficient significant correlation in the data for factor analysis (Chisq(2211) = 38924.86, p < .001).</pre>
```

Figure 2: Output of preliminary testing for the data. The Kaiser-Meyer-Olkin (KMO) test measure is 0.92. According to Kaiser, values of KMO > 0.9 are marvelous. Bartlett's test of sphericity tests the hypothesis of whether the correlation matrix is an identity matrix. If the null hypothesis is rejected, then we can assume the variables are correlated. Here, the test suggests that the data is significantly correlated and suitable for factor analysis.

From Figure 2, we confirm that factor analysis is the right approach to take for making inference about the data. We expect promising results from this insight, and can move on to determining how many factors we should attempt to extrapolate. Figure 3 shows the scree plot applied to the data.

There is not a unique solution to EFA, but we have two metrics that determined 15 factors is the optimal number to estimate. Considering the number of variables we started with, we believe

Non Graphical Solutions to Scree Test

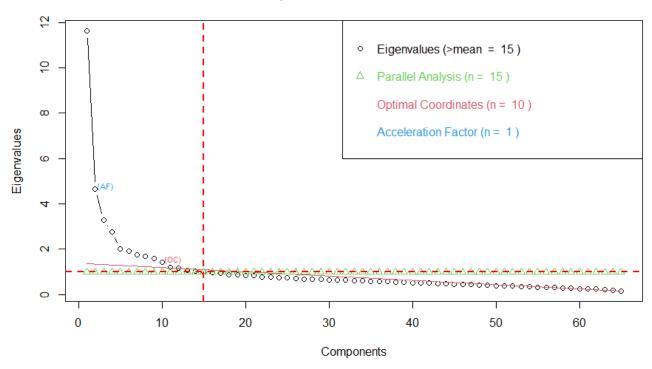

Figure 3: Scree plot applied to survey data. Dashed, red lines at y=1 and x=15 indicate the eigenvalue threshold of 1.0 and the largest number of suggested components, respectively. The intersection of these lines is the "optimal" target for factors that should be included.

this is a conservative yet suitable value for interpretability. In this scenario, it does not make sense to test 14 or 16 factors since the adjacent suggested value is 10, and the eigenvalues beyond 15 factors fall below 1.0.

The factor analysis is performed with the fa() function, which uses maximum-likelihood for fitting. The following parameter options were supplied:

- rotation = "oblimin" Since is study prioritizes uncovering associations between variables, it is less compelling to assume independence among them, even though orthogonal rotations are generally simpler to interpret. The difference is also not significant for this data, so oblimin is preferred.
- scores = "regression" Thompson's regression method that estimates the unknown element vector of scores f on element vector x to yield $\hat{f} = \Lambda' \Sigma^{-1} x$, where Λ is a matrix of loadings and Σ the correlation matrix of x (Revelle, 2023).

The resulting loadings are listed in the table on page 11 (Figure 4), with our interpretations for each grouping of variables.

3.2 Model Estimation & Evaluation

A multi-stage SEM approach (model specification, model identification, model estimation and evaluation, and model modification) was employed in order to evaluate the 15 loadings fitted from the factor analysis. Model specification was comprised of defining relationships among the loadings. Upon confirmation of model identification, subsequent models were evaluated by using a variety of recommended indices such as, chi-square, comparative fit index (CFI), and Tucker-Lewis Index (TLI), root mean square error of approximation (RMSEA), and standardized root mean square residual (SRMR) (Kline, 2010). For the CFI and TLI, a value \geq .90 was considered acceptable, and a value \geq .95 considered a good fit (Hu & Bentler, 1999). For the SRMR, a value of < .05 was considered a good fit. Less emphasis is placed on the chi-squared outcomes due to its sensitivity to large samples (Hu & Bentler, 1999).

Figure 4: Table of the variables, loadings, and the factors that will serve as the basis for the SEM model. Descriptions and names for each factor are provided. The variables highlighted in purple are below the moderate correlation threshold of 0.2, and provide no significant contribution to the factor of which they are assigned.

The initial hypothesized model, sem_full, aimed to include all 15 factor variables (covariates) to evaluate the fit of all the loadings produced from the factor analysis ($\chi^2/\text{df} = 4147.915$, p < 0.001, CFI = 0.881, TLI = 0.867, RMSEA = 0.042, SRMR = 0.049). Model modification was then conducted to remove non-significant pathways, yielding new and reduced models. Figure 4 and Figure 5 show the final structural models that yielded from model modification, focusing on the outcomes of anxiety and depression, respectively.

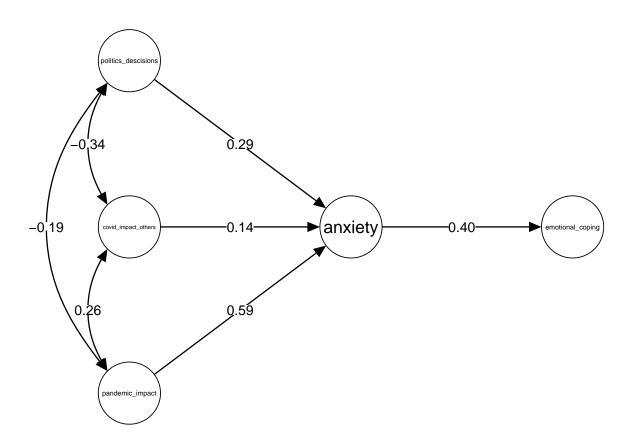

Figure 5: SEM_Anxiety. Structural equation model with standardized loadings focusing on anxiety outcomes. N = 1,450. Politics_decisions: Respondent's decision making habits influenced by their political ideology; Covid_impact_others: COVID-19 diagnosis and prognosis outcomes for people in respondent's life; Pandemic_impact: Impact of COVID-19 pandemic on aspects of respondent's well-being; Anxiety: Symptions of anxiety (GAD) from GAD7 screening questions; Emotional_coping: Coping mechanisms to target emotional resiliancy; focused on psyhological well-being.

The structural equation model for anxiety, sem_anxiety, presented an adequate fit $(\chi^2/df =$

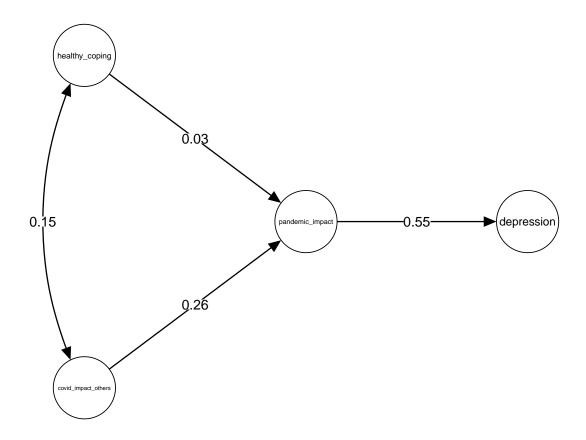

Figure 6: SEM_Depression. Structural equation model with standardized loadings focusing on depression outcomes. N=1,450. Healthy_coping: Positive and healthy coping mechanisms; focused on physiological well-being; Covid_impact_others: COVID-19 diagnosis and prognosis outcomes for people in respondent's life; Pandemic_impact: Impact of COVID-19 pandemic on aspects of respondent's well-being; Depression: Symptoms of depression from PHQ9 screening questions, with potential for unhealthy coping mechanicms via alcohol/drugs.

658.569, p < 0.001, CFI = 0.951, TLI = 0.943, RMSEA = 0.046, SRMR = 0.044). This model also included five covariates: political_decisions, covid_impact_others, pandemic_impact, anxiety, and emotional_coping. There were significant positive main effects between a respondent's symptoms of anxiety (based on the GAD7 anxiety screening questions on the participant questionnaire) and the following: a respondent's decision making habits influenced by their political ideology ($\beta = 0.29$, p = 0.003), a respondent's COVID-19 diagnosis and prognosis outcomes for people in their life ($\beta = 0.14$, p = 0.042), and a respondent's impact of COVID-19 pandemic on aspects of their well-being ($\beta = 0.59$, p < 0.001). Additionally, there were significant effects on a respondent's symptoms of anxiety and a respondent's ability to use coping mechanisms to target emotional resiliency; focused on psychological well-being ($\beta = 0.40$, p < 0.001). All five covariates in this model were significantly associated (p < 0.05).

The structural equation model for depression, sem_depression, presented an relatively adequate fit ($\chi^2/\text{df} = 1010.902$, p < 0.001, CFI = 0.929, TLI = 0.920, RMSEA = 0.055, SRMR = 0.040). This model included four covariates: healthy_coping, covid_impact_others, pandemic_impact, and depression. There was a significant main effect of the impact on a respondent's symptoms of depression (based on the PHQ9 screening questions from the participant questionnaire) with potential for unhealthy coping mechanics via alcohol/drugs and on the impact of COVID-19 pandemic on aspects of the respondent's well-being ($\beta = 0.55$, p < 0.001). Additionally, there was a significant effect on the impact of the COVID-19 pandemic on aspects of the respondent's well-being and the effect of a respondent's COVID-19 diagnosis and prognosis outcomes for people in respondent's life ($\beta = 0.26$, p < 0.001). All four covariates in this model were significantly associated (p < 0.001), with the exception of a respondent's positive and healthy coping mechanisms focused on physiological well-being and the impact of COVID-19 pandemic on aspects of respondent's well-being ($\beta = 0.03$, p < 0.431).

4 Discussion

The current study investigated the associations between various factors surrounding the COVID-19 pandemic and anti-Black racism that influence the extent to which Black women suffer from depression, anxiety, and other mental health issues. Our results demonstrated significant associations between a respondent's symptoms of anxiety, decision making habits influenced by their political ideology, COVID-19 diagnosis and prognosis outcomes for people in respondent's life, and the impact of the COVID-19 pandemic on aspects of respondent's well-being.

Additionally, results also displayed significant associations between a respondent's symptoms of depression with potential for unhealthy coping mechanics via alcohol/drugs, and the impact of the COVID-19 pandemic on aspects of respondent's well-being. Lastly, results indicated significant associations between a respondent's symptoms of anxiety and the coping mechanisms they use to target emotional resiliency, focused on psychological well-being.

The associations uncovered from the analysis demonstrate the need for awareness regarding the lack of adequate mental health resources for vulnerable populations residing in the United States, like Black women. Our client expressed a desire to pursue this research because it contributes to a greater understanding of the risks involved in blanket public policies that can undermine the needs of those who are not immediately "visible" in socioeconomic and political contexts. For an analogous example, public discourse on reproductive rights are narrowly focused on the experience of being a woman, and often neglect the nuances of those who do not identify as women, but are impacted nonetheless (i.e. transgender men and non-binary people).

The implication of this study and its results align with what we already assumed to be true: access to personal care is not equitable across intersectional dimensions of identity, and this issue is self-reinforcing when members of said demographics—Black women—are not allowed a space or voice to express their experiences. Identifying interventions that have the potential to change that narrative are beyond the scope of our contributions in this research, but we can conclude that providing productive coping mechanisms and emotional support are key to answering a simple question, "Sis, are you okay?"
